

# Introduction to programming using Python

Session 2

Matthieu Choplin

matthieu.choplin1@city.ac.uk

http://moodle.city.ac.uk/

#### Objectives

- Review what we have seen in the previous session:
  - Variables
  - Data types
  - Functions
- Controlling the flow of our programs

#### Variables 1: dynamic typing

- Python has strong dynamic typing
  - No need to declare the type of the variable
  - Python recognises the type according to the value of the variable

```
my_variable = 100
print(type(my_variable)) # will print <class 'int'>
my_variable="100" # notice the quote for a string data type
print(type(my_variable)) # will print <class 'str'>
```

#### Variables 2: case sensitive

Python is case sensitive

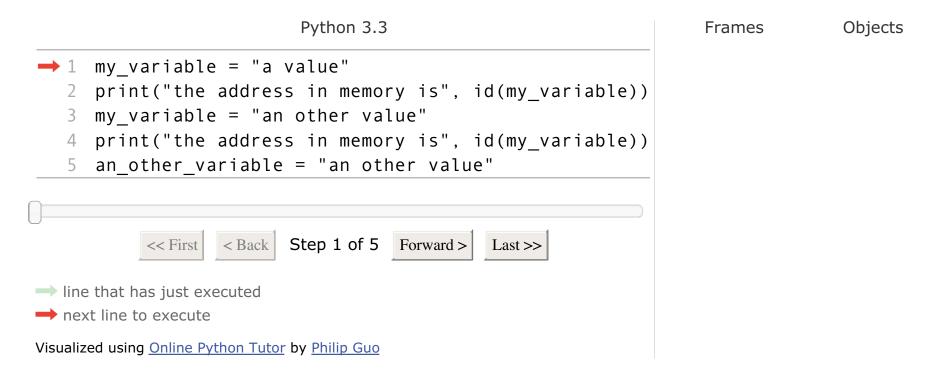

```
My_variable = 100
print(id(My_variable))
Traceback (most recent call last):
   File "<stdin>", line 1, in <module>
NameError: name 'my_variable' is not defined
```

#### Variables 3: where it is stored

A variable has an address in memory

#### Variables 4: scope

- A variable has a **scope**: only accessible from where it is defined.
- A variable is wiped out from memory once it stopped being used. We say that is it garbage collected

We define variable\_a in program\_a.py

```
#program_a.py
variable_a = 42
```

We try to use variable\_a in program\_b.py. What is wrong?

```
#program_b.py
print(variable_a)
```

#### Variables 5: naming rules

- A variable name is a non-empty sequence of characters of any length with:
  - The start character can be the underscore "\_" or a capital or lower case letter.
  - Python keywords are not allowed as identifier names!

### Keywords (to not use as variable name)

and	as	assert	break	class	continue	def	del
elif	else	except	exec	finally	for	from	global
if	import	in	is	lambda	not	or	pass
print	raise	return	try	while	with	yield	

### Exercise 1: From algorithm to Python code

- Translate the following algorithm into Python code:
  - Step 1: Use a variable named miles with initial value 100.
  - Step 2: Multiply miles by 1.609 and assign it to a variable named kilometers
  - Step 3: Display the value of kilometers
- Show solution

#### Exercise 2.1: Area of a squared room

- The length and width are hardcoded variables for now.
- Use variables (for length, width and area)
- The multiply operator in Python is the sign\*
- Formulae of the area of a square: length \* width
- Use the **print()** function to display the result
- Show solution

#### Exercise 2.2: Dynamic Area

- The length and width are dynamic variables now.
- Use the input() function for taking the values from the user.
- Convert the input received into a number with the function float()
- Show solution

#### Common Data Types: definition

- Numeric types:
  - Integer: whole number

```
type(1) # <class 'int'>
```

Float: number with decimal

String

## Common Data Types: Examples

Data type	Examples
Integers	-2, -1, 0, 1, 2, 3, 4, 5
Floats	-1.25, -1.0,0.5, 0.0, 0.5, 1.0, 1.25
Strings	'a', 'aa', 'aaa', 'Hello!', '11 cats'

# Numeric Operators

Name	Meaning	Example	Result
+	Addition	34 + 1	35
_	Substraction	34.0 - 0.1	33.9
*	Multiplication	300 * 30	9000
/	Float division	1/2	0.5
//	Integer Division	1//2	0
**	Exponentiation	4 ** 0.5	2.0
%	Remainder	20 % 3	2

## The % (modulo or remainder) operator (1/2)

### The % (modulo or remainder) operator (2/2)

Remainder is very useful in programming. For example, an even number % 2 is always 0 and an odd number % 2 is always 1. So you can use this property to determine whether a number is even or odd.

#### Arithmetic expressions

$$\frac{3+4x}{5} - \frac{10(y-5)(a+b+c)}{x} + 9(\frac{4}{x} + \frac{9+x}{y})$$

...is translated to:

NB: the sign \ is an "escaped" character, to break a line for readability

#### Exercise: Computing Loan Payments

Let the user enter the interest rate, number of years, and loan amount, and computes monthly payment and total payment.

- Use input()
- Translate the following arithmetic expression in Python:

$$monthlyPayment = \frac{loanAmount \times monthlyInterestRate}{1 - \frac{1}{(1 + monthlyInterestRate)^{numberOfYears \times 12}}}$$

## Solution: Computing Loan Payments

Show solution

## Operations on the String Type (1/2)

Concatenation

The expression concatenating a string returns a new string:

## Operations on the String Type (2/2)

Slicing

Remember that the string is a **sequence** of characters

The items of a sequence can be accessed through indexes

Items	a	b	r	a	C	a	d	a	b	r	a	
(characters)												
Indexes	0	1	2	3	4	5	6	7	8	9	10	_

Get the first element of the sequence:

first\_elem = abracadabra[0]

#### Built in functions seen so far

- Input/Ouput
  - input()
  - print()
- Conversion type:
  - int()
  - float()
  - **str()**
- Introspection:
  - type()
  - dir()
  - help()
  - **-** id()

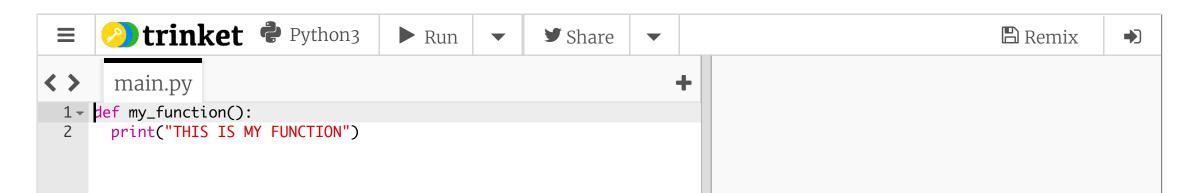

#### Defining our own function

To define a function, we use the keyword **def**, the name of the function, the brackets, and the colon

Then the body of the function needs to be indented

```
def name_of_the_function():
    # body of the function
```

When we define a function, we just make python see that the function exist but it is not executed

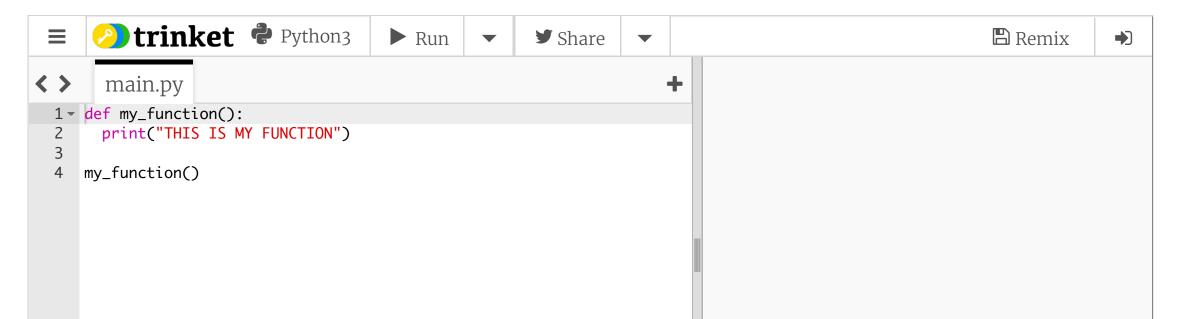

#### Calling our own function

To call or execute or run a function, we use the name of the function AND the brackets, without the brackets, the function is not called.

```
name_of_the_function()
```

Notice the difference between defining and calling a function

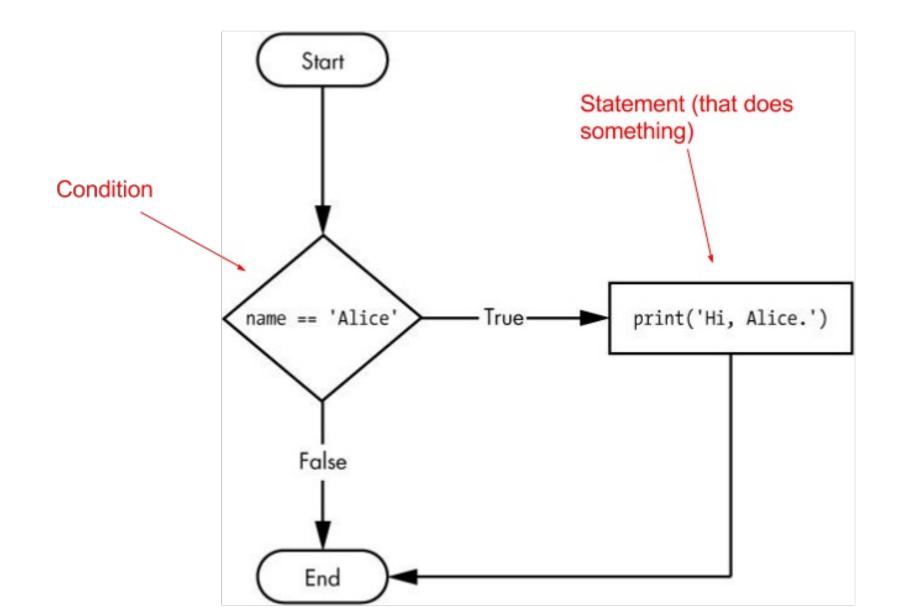

### Controlling the flow of our programs

We can represent the flow of execution with a flow chart

#### Structure of a simple if statement

Pseudo code:

```
if condition:
    # statement (mind the indentation)
```

Example, representation of the flow chart example in python code:

```
if name=='Alice':
    print('Hi Alice')
```

#### The two-way if statement

Pseudo code:

```
if condition:
    # statement (mind the indentation)
else:
    # statement executed when the condition is False
```

Example, representation of the flow chart example in python code with an else statement:

```
if name=='Alice':
    print('Hi Alice')
else:
    print('Hi')
```

#### Multiple Alternative if Statements

#### The naive way

```
if condition:
    # statement (mind the indentation)
else:
    if:
        # statement executed when
        # the previous condition is False
    else:
        # statement executed when none of
        # the previous condition is verified
```

#### Multiple Alternative if Statements

The better way, the pythonc way

```
if condition:
    # statement (mind the indentation)
elif:
    # statement executed when
    # the previous condition is False
elif:
    # statement executed when none of
    # the previous condition is verified
else:
    # executed when all conditions are False
```

#### Value of the condition

The program will execute statement only if the condition is verified. Only if the condition is True.

The condition is actually a **boolean**.

#### The Boolean Type

- It has only 2 possible values: **True** or **False**. Notice that they are both capitalized, which is important because Python is case sensitive
- It is often obtained as a result of a comparison expression.

## The Comparison Operators

Operator	Meaning
<	less than
<=	less than or equal
>	greater than
>=	greater than or equal
==	equal to
!=	not equal to

## Examples

```
      Emix
      ▶

      Python3
      >_ Run
      ▼
      Share
      ▼

      Powered by Strinket Connecting to server -
      Connecting to server -
      ■

      1 'hello' == 'hello'
      2 'hello' == 'tallo'
      True == True
      True != False

      6 42 == 42.0
      7 42 == '42'
      42 == '42'
```

#### Difference between '==' and '='

- The sign = is the sign of **assignment**, it is used for assigning a value to a variable
- The sign == is the sign of **comparison**, it compares 2 values and return a boolean (True or False)

#### Truth tables

Show every possible result of a Boolean operator.

The **and** Operator's Truth Table

Expression	Evaluates to
True and True	True
True and False	False
False and True	False
False and False	False

#### The **or** Operator's Truth Table

Expression	Evaluates to
True or True	True
True or False	True
False or True	True
False or False	False

#### The **not** Operator

It operates on only one Boolean value (or expression). The not operator simply evaluates to the opposite Boolean value.

```
Timket Python3 >= Run Share Powered by Trinket Connecting to server Interval And In
```

#### Exercise: control flow

Write a program that prompts the user to enter an integer. If the number is a multiple of 5, print HiFive. If the number is divisible by 2, print HiEven.

- Use input() take the user input
- Use int() to convert the value return by input into an integer
- Use % to see if a number x is divisible by an other number y, if x%y returns 0, then x is divisible by y
- Use print()

#### Solution: control flow

Show solution

#### Exercise: grading students

Write a program that is going to give the grade of a student according to the score obtained.

- Display 'A' if the score is greater than 90
- Display 'B' if the score is between 80 and 90
- Display 'C' if the score is between 70 and 80
- Display 'D' if the score is between 60 and 70
- Display 'F' if the score is lower than 60

## Solution: grading students

Show solution

#### Exercise: determining a leap year

This program first prompts the user to enter a year as an int value and checks if it is a leap year.

A year is a leap year if it is divisible by 4 but not by 100, or it is divisible by 400.

- Use input() to take the user input (the year, i.e. 2016) and convert it with int()
- Use % to see if a number x is divisible by an other number y, if x%y returns 0, then x is divisible by y
- Check if the year is divisible by 4 AND not divisible by 100
- OR check if the year is divisible by 400.
- Use print()

## Solution: determining a leap year

- Condition to use
- Complete solution

#### Exercise: Chinese Zodiac sign

Now let us write a program to find out the Chinese Zodiac sign for a given year. The Chinese Zodiac sign is based on a **12-year cycle**, each year being represented by an animal: rat, ox, tiger, rabbit, dragon, snake, horse, sheep, monkey, rooster, dog, and pig, in this cycle

Hint
